

A Tutorial for the Odespy Interface to ODE Solvers

Hans Petter Langtangen* Liwei Wang†

Sep 19, 2013

The Odespy package makes it easy to specify an ODE problem in Python and get it solved by a wide variety of different numerical methods and software.

1 Motivation

The Odespy package grew out of the desire to have a unified interface to lots of different methods and software for ODEs. Consider the ODE problem

$$y'' = 3(1 - y^2)y' - y, \quad y(0) = 2, \quad y'(0) = 1,$$

known as the van der Pool oscillator. The solution is desired at 150 equally spaced time levels in the interval $[0, 30]$.

1.1 Traditional Approach

We want to solve this problem by three well-known routines:

1. `LSODE` from ODEPACK (adaptive Adams and BDF methods)
2. `ode45` from MATLAB (adaptive Runge-Kutta 4-5-th order)
3. `vode` from Python (adaptive Adams and BDF methods)

All of these routines require the ODE problem to be on the form $u' = f(u, t)$, which means that the second-order differential equation must be recast as a system of two ODEs,

$$\frac{d}{dt}u^{(0)} = u^{(1)}, \quad \frac{d}{dt}u^{(1)} = 3(1 - (u^{(0)})^2)u^{(1)} - u^{(0)},$$

and we have to identify the two components of the $f(u, t)$ function:

$$f^{(0)}(u^{(0)}, u^{(1)}, t) = u^{(1)}, \quad f^{(1)}(u^{(0)}, u^{(1)}, t) = 3(1 - (u^{(0)})^2)u^{(1)} - u^{(0)}$$

*Center for Biomedical Computing, Simula Research Laboratory and Department of Informatics, University of Oslo.

†Department of Informatics, University of Oslo.

The corresponding boundary conditions become

$$u^{(0)}(0) = 2, \quad u^{(1)}(0) = 1.$$

The mentioned ODE software needs a specification of the $f(u, t)$ formulas through some user-written function that takes u and t as input and delivers the vector f as output.

LSODE. Application of LSODE and other ODEPACK routines requires the ODE problem to be specified in FORTRAN and the solver to be called from FORTRAN:

```

PROGRAM MAIN
EXTERNAL F
INTEGER I, IOPT, IOUT, ISTATE, ITASK, ITOL, IWORK,
1 LRW, LIW, MF, NEQ, NOUT
DOUBLE PRECISION ATOL, T, TOUT, RTOL, RWORK, U, URR
DIMENSION U(2), RWORK(52), IWORK(20), U1(5), U2(5)
NEQ = 2
C SET ADAMS METHOD:
MF = 10
C LET TOLERANCES BE SCALARS (NOT ARRAYS):
ITOL = 1
C USE ONLY ABSOLUTE TOLERANCE:
RTOL = 0.0D0
ATOL = 1.0D-6
LRW = 52
LIW = 20
C NUMBER OF TIME STEPS:
NOUT = 150
C FINAL TIME:
TOUT = 30.0D0
C INITIAL CONDITIONS
T = 0.0D0
U(1) = 2.0D0
U(2) = 0.0D0
ITASK = 1
ISTATE = 1
C CALL ADAPTIVE TIME STEPPING AT EACH OF THE TARGET TIME LEVELS
DO 100 IOUT = 1, NOUT
CALL DLSODE(F, NEQ, U, T, TOUT, ITOL, RTOL, ATOL, ITASK,
1 ISTATE, IOPT, RWORK, LRW, IWORK, LIW, JAC, MF)
U1(IOUT) = U(1)
U2(IOUT) = U(2)
TOUT = TOUT + 2.0D-1
100 CONTINUE
END

SUBROUTINE F(NEQ, T, U, UDOT)
INTEGER NEQ
DOUBLE PRECISION T, U, UDOT
DIMENSION U(2), UDOT(2)
UDOT(1) = U(2)
UDOT(2) = 3.0D0*(1.0D0 - U(1)*U(1))*U(2) - U(1)
RETURN
END

```

MATLAB. The problem can be solved with very compact code in MATLAB. The definition of the ODE system, the $f(u, t)$ function, is placed in a function in a file, say `myode.m`:

```
function F = myode(t, u);
F(1,1) = u(2)
F(2,1) = 3*(1 - u(1)*u(1))*u(2) - u(1)
```

In MATLAB we can then solve the problem by

```
>> options = odeset('RelTol',0.0,'AbsTol',1e-6);
>> tspan = [0 30];
>> u0 = [2; 0]
>> [t, u] = ode45('myode', tspan, u0, options);
```

Python. Calling up the `vode` method from the `scipy` library in Python also results in fairly compact code:

```
def f(t, u):
    return [u[1], 3.*(1. - u[0]*u[0])*u[1] - u[0]]

from scipy.integrate import ode
r = ode(f).set_integrator('vode', method='adams',
                        order=10, r0l=0, atol=1e-6,
                        with_jacobian=False)

u0 = [2.0, 0.0]
r.set_initial_value(u0, 0)
T = 30
dt = T/150.
u = []; t = []
while r.successful() and r.t <= T:
    r.integrate(r.t + dt)
    u.append(r.y); t.append(r.t)
```

Suppose you want to compare these methods and their implementations. This requires three different main programs and (worse) three different implementations of the definition of the mathematical problem. Some specifications of f has the signature $f(u, t)$ while others require $f(t, u)$, and such differences between packages are often a cause of programming errors.

1.2 Odespy's Unified Interface

The Odespy package provides a unified interface to all the three mentioned types of methods, which makes it easy to run all of them in a loop (program `motivation.py`):

```
def f(u, t):
    return [u[1], 3.*(1. - u[0]*u[0])*u[1] - u[0]]

u0 = [2.0, 0.0]
import odespy, numpy

for method in odespy.Lsode, odespy.DormandPrince, odespy.Vode:

    solver = method(f, rtol=0.0, atol=1e-6,
                    adams_or_bdf='adams', order=10)
    solver.set_initial_condition(u0)
    t_points = numpy.linspace(0, 30, 150)
    u, t = solver.solve(t_points)
```

Note in particular that the same `f` and the same call syntax can be reused across methods and the underlying software.

1.3 Methods and Implementations Offered by Odespy

Odespy features a unified interface to the following collection of numerical methods and implementations:

- Pure Python implementations of classical explicit schemes such as the Forward Euler method (also called Euler); Runge-Kutta methods of 2nd, 3rd, and 4th order; Heun's method; Adams-Bashforth methods of 2nd, 3rd, and 4th order; Adams-Bashforth-Moulton methods of 2nd and 3rd order.
- Pure Python implementations of classical implicit schemes such as Backward Euler; 2-step backward scheme; the θ rule; the Midpoint (or Trapezoidal) method.
- Pure Python implementations of adaptive explicit Runge-Kutta methods of type Runge-Kutta-Fehlberg of order (4,5), Dormand-Prince of order (4,5), Cash-Karp of order (4,5), Bogacki-Shampine of order (2,3).
- Wrappers for all FORTRAN solvers in [ODEPACK](#).
- Wrappers for the wrappers of FORTRAN solvers in [scipy](#): `vode` and `zvode` (adaptive Adams or BDF from [vode.f](#)); `dopri5` (adaptive Dormand-Prince method of order (4,5)); `dop853` (adaptive Dormand-Prince method of order 8(5,3)); `odeint` (adaptive switching between Adams or BDF from the implementation LSODA in [ODEPACK](#)).
- Wrapper for the Runge-Kutta-Chebyshev formulas of order 2 as offered by the well-known FORTRAN code [rkc.f](#).
- Wrapper for the Runge-Kutta-Fehlberg method of order (4,5) as provided by the well-known FORTRAN code [rkf45.f](#).
- Wrapper for the Radau5 method as provided by the well-known FORTRAN code [radau5.f](#).
- Wrapper for some solvers in the [odelab](#) package.

The ODE problem can always be specified in Python, but for wrappers of FORTRAN codes one can also implement the problem in FORTRAN and avoid callback to Python.

2 Installation

The Odespy package is most easily installed by checking out the latest version of the source code:

```
git clone git@github.com:hplgit/odespy.git
cd odespy
```

The installation follows the standard procedure,

```
sudo python setup.py install
```

You will at least also need Python v2.7 and the [numpy](#) package. The FORTRAN codes `rkc.f`, `rkf45.f`, `radau5.f`, and ODEPACK comes with Odespy and are compiled and installed by `setup.py`.

The Odespy package depends on several additional packages:

- [scipy](#) for running the Vode Adams/BDF solver, the Dormand-Prince adaptive methods Dop853, and Dopri5, and the [scipy](#) wrapper `odeint` of the FORTRAN code LSODA (Odespy features an alternative wrapper of the latter, in class `Lsoda`).
- [sympy](#) for running the extremely accurate `odefun_sympy` solver.
- [odelab](#) for accessing solvers in that package.

For plotting you will need [matplotlib](#) or [scitools](#).

These packages are readily downloaded and installed by the standard `setup.py` script, as shown above. On Ubuntu and other Debian-based Linux systems the following line installs all that Odespy may need:

```
sudo apt-get install python-scipy python-nose python-sympy \
python-matplotlib python-scitools python-pip
```

The `odelab` package is installed by either

```
pip install -e git+https://github.com/olivierverdier/odelab#egg=odelab
```

or downloading the source and running `setup.py`:

```
git clone git://github.com/olivierverdier/odelab.git
cd odelab
sudo python setup.py install
```

3 Basic Usage

This section explains how to use Odespy. The general principles and program steps are first explained. Thereafter, we present a series of examples with progressive complexity with respect to Python constructs and numerical methods.

3.1 Overview

A code using Odespy to solve ODEs consists of six steps. These are outlined in generic form below.

Step 1. *Write the ODE problem in generic form $u' = f(u, t)$, where $u(t)$ is the unknown function to be solved for, or a vector of unknown functions of time in case of a system of ODEs.*

Step 2. *Implement the right-hand side function $f(u, t)$ as a Python function `f(u, t)`. The argument `u` is either a `float` object, in case of a scalar ODE, or a `numpy` array object, in case of a system of ODEs. Some solvers in this package also allow implementation of f in FORTRAN for increased efficiency.*

Step 3. *Create a solver object*

```
solver = classname(f)
```

where `classname` is the name of a class in this package implementing the desired numerical method.

Many solver classes has a range of parameters that the user can set to control various parts of the solution process. The parameters are documented in the doc string of the class (`pydoc classname` will list the documentation in a terminal window). One can either specify parameters at construction time, via extra keyword arguments to the constructor,

```
solver = classname(f, prm1=value1, prm2=value2, ...)
```

or at any time using the `set` method:

```
solver.set(prm1=value1, prm2=value2, prm3=value3)
...
solver.set(prm4=value4)
```

Step 4. *Set the initial condition $u(0) = U_0$,*

```
solver.set_initial_condition(U0)
```

where `U0` is either a number, for a scalar ODE, or a sequence (list, tuple, `numpy` array), for a system of ODEs.

Step 5. *Solve the ODE problem, which means to compute $u(t)$ at some discrete user-specified time points t_1, t_2, \dots, t_N .*

```
T = ... # end time
time_points = numpy.linspace(0, T, N+1)
u, t = solver.solve(time_points)
```

In case of a scalar ODE, the returned solution `u` is a one-dimensional `numpy` array where `u[i]` holds the solution at time point `t[i]`. For a system of ODEs, the returned `u` is a two-dimensional `numpy` array where `u[i, j]` holds the solution of the j -th unknown function at the i -th time point `t[i]` ($u_j(t_i)$ in mathematics notation).

By giving the parameter `disk_storage=True` to the solver's constructor, the returned `u` array is memory mapped (i.e., of type `numpy.memmap`) such that all the data are stored on file, but parts of the array can be efficiently accessed.

The `time_points` array specifies the time points where we want the solution to be computed. The returned array `t` is the same as `time_points`. The simplest numerical methods in the Odespy package apply the `time_points` array directly for the time stepping. That is, the time steps used are given by

```
time_points[i] - time_points[i-1] # i=0,1,...,len(time_points)-1
```

The adaptive schemes typically compute between each time point in the `time_points` array, making this array a specification where values of the unknowns are desired.

The `solve` method in solver classes also allows a second argument, `terminate`, which is a user-implemented Python function specifying when the solution process is to be terminated. For example, terminating when the solution reaches an asymptotic (known) value `a` can be done by

```
def terminate(u, t, step_no):
    # u and t are arrays. Most recent solution is u[step_no].
    tolerance = 1E-6
    return abs(u[step_no] - a) < tolerance

u, t = solver.solve(time_points, terminate)
```

The arguments transferred to the `terminate` function are the solution array `u`, the corresponding time points `t`, and an integer `step_no` reflecting the most recently computed `u` value. That is, `u[step_no]` is most recently computed value of `u`. (The array data `u[step_no+1:]` will typically be zero as these are uncomputed future values.)

Step 6. *Extract solution components* for plotting and further analysis. Since the `u` array returned from `solver.solve` stores all unknown functions at all discrete time levels, one usually wants to extract individual unknowns as one-dimensional arrays. Here is an example where unknown number 0 and `k` are extracted in individual arrays and plotted:

```
u_0 = u[:,0]
u_k = u[:,k]

from matplotlib.pyplot import plot, show
plot(t, u_0, t, u_k)
show()
```

3.2 First Example: Logistic Growth

Our first example concerns the simple scalar ODE problem

$$\frac{du}{dt} = au \left(1 - \frac{u}{R}\right), \quad u(0) = A,$$

where $A > 0$, $a > 0$, and $R > 0$ are known constants. This is a common model for population dynamics in ecology where u is the number of individuals,

a the initial growth rate, R is the maximum number of individuals that the environment allows (the so-called *carrying capacity* of the environment).

Using a standard Runge-Kutta method of order four, the code for solving the problem in the time interval $[0, 10]$ with $N = 30$ time steps, looks like this (program `logistic1.py`):

```
def f(u, t):
    return a*u*(1 - u/R)

a = 2
R = 1E+5
A = 1

import odespy
solver = odespy.RK4(f)
solver.set_initial_condition(A)

from numpy import linspace, exp
T = 10 # end of simulation
N = 30 # no of time steps
time_points = linspace(0, T, N+1)
u, t = solver.solve(time_points)
```

With the RK4 method and other non-adaptive methods the time steps are dictated by the `time_points` array. A constant time step of size is implied in the present example. Running an alternative numerical method just means replacing RK4 by, e.g., RK2, ForwardEuler, BackwardEuler, AdamsBashforth2, etc.

We can easily plot the numerical solution and compare with the exact solution (which is known for this equation):

```
def u_exact(t):
    return R*A*exp(a*t)/(R + A*(exp(a*t) - 1))

from matplotlib.pyplot import *

plot(t, u, 'r-',
      t, u_exact(t), 'bo')
savefig('tmp.png')
show()
```

All the examples in this tutorial are found in the GitHub directory <https://github.com/hplgit/odespy/tree/master/doc/src/odespy/src-odespy/>. If you download the tarball or clone the GitHub repository, the examples reside in the directory `doc/src/odespy/src-odespy`.

3.3 Parameters in the Right-Hand Side Function

The right-hand side function and all physical parameters are often lumped together in a class, for instance,

```
class Logistic:
    def __init__(self, a, R, A):
        self.a = a
        self.R = R
        self.A = A
```

Figure 1: Solution of the logistic equation with the 4-th order Runge-Kutta method (solid line) and comparison with the exact solution (dots).

```
def f(self, u, t):
    a, R = self.a, self.R # short form
    return a*u*(1 - u/R)

def u_exact(self, t):
    a, R, A = self.a, self.R, self.A # short form
    return R*A*exp(a*t)/(R + A*(exp(a*t) - 1))
```

Note that introducing local variables like `a` and `R`, instead of using `self.a` and `self.A`, makes the code closer to the mathematics. This can be convenient when proof reading the implementation of complicated ODEs.

The numerical solution is computed by

```
import odespy
problem = Logistic(a=2, R=1E+5, A=1)
solver = odespy.RK4(problem.f)
solver.set_initial_condition(problem.A)

T = 10 # end of simulation
N = 30 # no of time steps
time_points = linspace(0, T, N+1)
u, t = solver.solve(time_points)
```

The complete program is available in the file program `logistic2.py`.

Instead of having the problem parameters `a` and `R` in the ODE as global variables or in a class, we may include them as extra arguments to `f`, either

as positional arguments or as keyword arguments. Positional arguments can be sent to `f` via the constructor argument `f_args` (a list/tuple of variables), while a dictionary `f_kwargs` is used to transfer keyword arguments to `f` via the constructor. Here is an example on using keyword arguments:

```
def f(u, t, a=1, R=1):
    return a*u*(1 - u/R)

A = 1

import odespy
solver = odespy.RK4(f, f_kwargs=dict(a=2, R=1E+5))
```

In general, a mix of positional and keyword arguments can be used in `f`:

```
def f(u, t, arg1, arg2, arg3, ..., kwarg1=val1, kwarg2=val2, ...):
    ...

solver = odespy.classname(f,
    f_args=[arg1, arg2, arg3, ...],
    f_kwargs=dict(kwarg1=val1, kwarg2=val2, ...))

# Alternative setting of f_args and f_kwargs
solver.set(f_args=[arg1, arg2, arg3, ...],
    f_kwargs=dict(kwarg1=val1, kwarg2=val2, ...))
```

Solvers will call `f` as `f(u, t, *f_args, **f_kwargs)`.

3.4 Continuing a Previous Simulation

It is easy to simulate for some time interval $[0, T_1]$, then continue with $u(T_1)$ as new initial condition and simulate for t in $[T_1, T_2]$ and so on. Let us divide the time domain into subdomains and compute the solution for each subdomain in sequence. The following program performs the steps ([logistic4.py](#)).

```
def f(u, t, a=1, R=1):
    return a*u*(1 - u/R)

A = 1

import odespy, numpy
from matplotlib.pyplot import plot, hold, show, axis

solver = odespy.RK4(f, f_kwargs=dict(a=2, R=1E+5))

# Split time domain into subdomains and
# integrate the ODE in each subdomain
T = [0, 1, 4, 8, 12] # subdomain boundaries

N_tot = 30 # total no of time steps
dt = float(T[-1])/N_tot # time step, kept fixed
u = []; t = [] # collectors for u and t in each domain

for i in range(len(T)-1):
    T_interval = T[i+1] - T[i]
    N = int(round(T_interval/dt))
    time_points = numpy.linspace(T[i], T[i+1], N+1)
```

```

solver.set_initial_condition(A) # at time_points[0]
print 'Solving in [%s, %s] with %d intervals' % \
      (T[i], T[i+1], N)
ui, ti = solver.solve(time_points)
A = ui[-1] # newest ui value is next initial condition

plot(ti, ui)
hold('on')

u.append(ui); t.append(ti)

axis([0, T[-1], -0.1E+5, 1.1E+5])
# Can concatenate all the elements of u and t, if desired
u = numpy.concatenate(u); t = numpy.concatenate(t)
savefig('tmp.png')

```

3.5 Termination Criterion for the Simulation

We know that the solution u of the logistic equation approaches R as $t \rightarrow \infty$. Instead of using a trial and error process for determining an appropriate time interval for integration, the `solver.solve` method accepts a user-defined function `terminate` that can be used to implement a criterion for terminating the solution process. Mathematically, the relevant criterion is $\|u - R\| < \text{tol}$, where `tol` is an acceptable tolerance, say 100 in the present case where $R = 10^5$. The `terminate` function implements the criterion and returns true if the criterion is met:

```

def terminate(u, t, step_no):
    """u[step_no] holds (the most recent) solution at t[step_no]."""
    return abs(u[step_no] - R) < tol:

```

Note that the simulation is anyway stopped for $t > T$ so T must be large enough for the termination criterion to be reached (if not, a warning will be issued). With a `terminate` function it is also convenient to specify the time step `dt` and not the total number of time steps.

A complete program can be as follows (`logistic5.py`):

```

def f(u, t):
    return a*u*(1 - u/R)

a = 2
R = 1E+5
A = 1

import odespy, numpy
solver = odespy.RK4(f)
solver.set_initial_condition(A)

T = 20 # end of simulation
dt = 0.25
N = int(round(T/dt))
time_points = numpy.linspace(0, T, N+1)

tol = 100 # tolerance for termination criterion

```

```

def terminate(u, t, step_no):
    """u[step_no] holds (the most recent) solution at t[step_no]."""
    return abs(u[step_no] - R) < tol:

u, t = solver.solve(time_points, terminate)
print 'Final u(t=%g)=%g' % (t[-1], u[-1])

from matplotlib.pyplot import *
plot(t, u, 'r-')
savefig('tmp.png')
show()

```

3.6 A Class-Based Implementation

The previous code example can be recast into a more class-based (“object-oriented programming”) example. We lump all data related to the problem (the “physics”) into a problem class `Logistic`, while all data related to the numerical solution and its quality are taken care of by class `Solver`. The code below illustrates the ideas (`logistic6.py`):

```

import numpy as np
import matplotlib.pyplot as mpl
import odespy

class Logistic:
    def __init__(self, a, R, A, T):
        """
        'a' is (initial growth rate), 'R' the carrying capacity,
        'A' the initial amount of u, and 'T' is some (very) total
        simulation time when 'u' is very close to the asymptotic
        value 'R'.
        """
        self.a, self.R, self.A = a, R, A
        self.tol = 0.01*R # tolerance for termination criterion

    def f(self, u, t):
        """Right-hand side of the ODE."""
        a, R = self.a, self.R # short form
        return a*u*(1 - u/R)

    def terminate(self, u, t, step_no):
        """u[step_no] holds solution at t[step_no]."""
        return abs(u[step_no] - self.R) < self.tol

    def u_exact(self, t):
        a, R, A = self.a, self.R, self.A # short form
        return R*A*np.exp(a*t)/(R + A*(np.exp(a*t) - 1))

class Solver:
    def __init__(self, problem, dt, method='RK4'):
        self.problem = problem
        self.dt = dt
        self.method_class = eval('odespy.' + method)
        self.N = int(round(T/dt))

    def solve(self):
        self.solver = self.method_class(self.problem.f)
        self.solver.set_initial_condition(self.problem.A)

```

```

        time_points = np.linspace(0, self.problem.T, self.N+1)
        self.u, self.t = self.solver.solve(
            time_points, self.problem.terminate)
        print 'Final u(t=%g)=%g' % (t[-1], u[-1])

    def plot(self):
        mpl.plot(self.t, self.u, 'r-',
                 self.t, self.u_exact(self.t), 'bo')
        mpl.legend(['numerical', 'exact'])
        mpl.savefig('tmp.png')
        mpl.show()

def main():
    problem = Logistic(a=2, R=1E+5, A=1, T=20)
    solver = Solver(problem, dt=0.25, method='RK4')
    solver.solve()
    solver.plot()

if __name__ == '__main__':
    main()

```

3.7 Using Other Symbols

The Odespy package applies `u` for the unknown function or vector of unknown functions and `t` as the name of the independent variable. Many problems involve other symbols for functions and independent variables. These symbols should be reflected in the user's code. For example, here is a coding example involving the logistic equation written as $y'(x) = ay(x)(1 - u(x)/R(x))$, where now a variable $R = R(x)$ is considered. Following the setup from the very first program above solving the logistic ODE, we can easily introduce our own nomenclature (`logistic7.py`):

```

def f(y, x):
    return a*y*(1 - y/R)

a = 2; R = 1E+5; A = 1

import odespy, numpy
solver = odespy.RK4(f)
solver.set_initial_condition(A)

L = 10 # end of x domain
N = 30 # no of time steps
x_points = numpy.linspace(0, L, N+1)
y, x = solver.solve(x_points)

from matplotlib.pyplot import *
plot(x, y, 'r-')
xlabel('x'); ylabel('y')
show()

```

As shown, we use `y` for `u`, `x` for `t`, and `x_points` instead of `time_points`.

3.8 Example: Solving an ODE System

We shall now explain how to solve a system of ODEs using a scalar second-order ODE as starting point. The angle θ of a pendulum with mass m and length L is

governed by the equation (neglecting air resistance for simplicity)

$$mL\ddot{\theta} + mg \sin \theta = 0, \quad \theta(0) = \Theta, \quad \dot{\theta}(0) = 0.$$

A dot over θ implies differentiation with respect to time. The ODE can be written as $\ddot{\theta} + c \sin \theta = 0$ by introducing $c = g/L$. This problem must be expressed as a first-order ODE system if it is going to be solved by the tools in the Odespy package. Introducing $\omega = \dot{\theta}$ (the angular velocity) as auxiliary unknown, we get the system

$$\begin{aligned}\dot{\theta} &= \omega, \\ \dot{\omega} &= -c \sin \theta,\end{aligned}$$

with $\theta(0) = \Theta$ and $\omega(0) = 0$.

Now the `f` function must return a list or array with the two right-hand side functions:

```
def f(u, t):
    theta, omega = u
    return [omega, -c*sin(theta)]
```

Note that when we have a system of ODEs with `n` components, the `u` object sent to the `f` function is an array of length `n`, representing the value of all components in the ODE system at time `t`. Here we extract the two components of `u` in separate local variables with names equal to what is used in the mathematical description of the current problem.

The initial conditions must be specified as a list:

```
solver = odespy.Heun(f)
solver.set_initial_condition([Theta, 0])
```

To specify the time points we here first decide on a number of periods (oscillations back and forth) to simulate and then on the time resolution of each period. Note that when Θ is small we can replace $\sin \theta$ by θ and find an analytical solution $\theta(t) = \Theta \cos(\sqrt{c}t)$ whose period is $2\pi/\sqrt{c}$. We use this expression as an approximation for the period also when Θ is not small.

```
freq = sqrt(c)           # frequency of oscillations when Theta is small
period = 2*pi/freq       # the period of the oscillations
T = 10*period            # final time
N_per_period = 20        # resolution of one period
N = N_per_period*period
time_points = numpy.linspace(0, T, N+1)

u, t = solver.solve(time_points)
```

The `u` returned from `solver.solve` is a two-dimensional array, where the columns hold the various solution functions of the ODE system. That is, the first column holds θ and the second column holds ω . For convenience we extract the individual solution components in individual arrays:

```

theta = u[:,0]
omega = u[:,1]

from matplotlib.pyplot import *
plot(t, theta, 'r-')
savefig('tmp.png')
show()

```

The complete program is available in the file `osc1a.py`.

Looking at the plot reveals that the numerical solution has an alarming feature: the amplitude grows (indicating increasing energy in the system). Changing T to 28 periods instead of 10 makes the numerical solution explode. The increasing amplitude is a numerical artifact that some of the simple solution methods suffer from.

Figure 2: Heun's method used to simulate oscillations of a pendulum.

Using a more sophisticated method, say the 4-th order Runge-Kutta method, is just a matter of substituting `Heun` by `RK4`:

```

solver = odespy.RK4(f)
solver.set_initial_condition([Theta, 0])
freq = sqrt(c)           # frequency of oscillations when Theta is small
period = 2*pi/freq       # the period of the oscillations
T = 10*period            # final time
N_per_period = 20        # resolution of one period
N = N_per_period*period
time_points = numpy.linspace(0, T, N+1)

u, t = solver.solve(time_points)

```

```

theta = u[:,0]
omega = u[:,1]

from matplotlib.pyplot import *
plot(t, theta, 'r-')
savefig('tmp.png')
show()

```

The amplitude now becomes constant in time as expected.

3.9 Testing Several Methods

We shall now make a more advanced solver by extending the previous example. More specifically, we shall

- represent the right-hand side function as class,
- compare several different solvers,
- compute error of numerical solutions.

Since we want to compare numerical errors in the various solvers we need a test problem where the exact solution is known. Approximating $\sin(\theta)$ by θ (valid for small θ), gives the ODE system

$$\begin{aligned}\dot{\theta} &= \omega, \\ \dot{\omega} &= -c\theta,\end{aligned}$$

with $\theta(0) = \Theta$ and $\omega(0) = 0$.

Right-hand side functions with parameters can be handled by including extra arguments via the `f_args` and `f_kwargs` functionality, or by using a class where the parameters are attributes and an `f` method defines $f(u, t)$. Section 3.3 exemplifies the details. A minimal class representation of the right-hand side function in the present case looks like this:

```

class Problem:
    def __init__(self, c, Theta):
        self.c, self.Theta = float(c), float(Theta)

    def f(self, u, t):
        theta, omega = u; c = self.c
        return [omega, -c*theta]

problem = Problem(c=1, Theta=pi/4)

```

It would be convenient to add an attribute `period` which holds an estimate of the period of oscillations as we need this for deciding on the complete time interval for solving the differential equations. An appropriate extension of class `Problem` is therefore

```

class Problem:
    def __init__(self, c, Theta):
        self.c, self.Theta = float(c), float(Theta)

```

```

        self.freq = sqrt(c)
        self.period = 2*pi/self.freq

    def f(self, u, t):
        theta, omega = u; c = self.c
        return [omega, -c*theta]

problem = Problem(c=1, Theta=pi/4)

```

The second extension is to loop over many solvers. All solvers can be listed by

```

>>> import odespy
>>> methods = list_all_solvers()
>>> for method in methods:
...     print method
...
AdamsBashMoulton2
AdamsBashMoulton3
AdamsBashforth2
...
Vode
lsoda_scipy
odefun_sympy
odelab

```

A similar function, `list_available_solvers`, returns a list of the names of the solvers that are available in the current installation (e.g., the `Vode` solver is only available if the comprehensive `scipy` package is installed). This is the list that is usually most relevant.

For now we explicitly choose a subset of the commonly available solvers:

```

import odespy
solvers = [
    odespy.ThetaRule(problem.f, theta=0),    # Forward Euler
    odespy.ThetaRule(problem.f, theta=0.5), # Midpoint method
    odespy.ThetaRule(problem.f, theta=1),    # Backward Euler
    odespy.RK4(problem.f),
    odespy.MidpointIter(problem.f, max_iter=2, eps_iter=0.01),
    odespy.LeapfrogFiltered(problem.f),
]

```

To see what a method is and its arguments to the constructor, invoke the doc string of the class, e.g., `help(ThetaRule)` inside a Python shell like IPython, or run `pydoc odespy.ThetaRule` in a terminal window, or invoke the [Odespy API documentation](#).

It will be evident that the `ThetaRule` solver with `theta=0` and `theta=1` (Forward and Backward Euler methods) gives growing and decaying amplitudes, respectively, while the other solvers are capable of reproducing the constant amplitude of the oscillations of in the current mathematical model.

The loop over the chosen solvers may look like

```

N_per_period = 20
T = 3*problem.period # final time
import numpy
import matplotlib.pyplot as plt
legends = []

```

```

for solver in solvers:
    solver_name = str(solver) # short description of solver
    print solver_name

    solver.set_initial_condition([problem.Theta, 0])
    N = N_per_period*problem.period
    time_points = numpy.linspace(0, T, N+1)

    u, t = solver.solve(time_points)

    theta = u[:,0]
    legends.append(solver_name)
    mpl.plot(t, theta)
    mpl.hold('on')
mpl.legend(legends)
mpl.savefig(__file__[:-3] + '.png')
mpl.show()

```

A complete program is available as [osc2.py](#).

Figure 3: Comparison of methods for solving the ODE system for a pendulum.

We can extend this program to compute the error in each numerical solution for different time step sizes. Let **results** be a dictionary with the method name as key, containing two sub dictionaries **dt** and **error**, which hold a sequence of time steps and a sequence of corresponding errors, respectively. The errors are computed by subtracting the numerical solution from the exact solution,

```

theta_exact = lambda t: problem.Theta*numpy.cos(sqrt(problem.c)*t)
u, t = solver.solve(time_points)

```

```
theta = u[:,0]
error = numpy.abs(theta_exact(t) - theta)
```

The so-called L2 norm of the `error` array is a suitable scalar error measure (square root of total error squared and integrated, here numerically):

```
error_L2 = sqrt(numpy.sum(error**2)/dt)
```

where `dt` is the time step size.

Typical loops over solvers and resolutions look as follows (`osc3.py`):

```
try:
    num_periods = int(sys.argv[1])
except IndexError:
    num_periods = 8 # default

T = num_periods*problem.period # final time
results = {}
resolutions = [10, 20, 40, 80, 160] # intervals per period
import numpy

for solver in solvers:
    solver_name = str(solver)
    results[solver_name] = {'dt': [], 'error': []}

    solver.set_initial_condition([problem.Theta, 0])

    for N_per_period in resolutions:
        N = N_per_period*num_periods
        time_points = numpy.linspace(0, T, N+1)

        u, t = solver.solve(time_points)

        theta = u[:,0]
        error = numpy.abs(theta_exact(t) - theta)
        error_L2 = sqrt(numpy.sum(error**2)/N)
        if not numpy.isnan(error_L2): # drop nan (overflow)
            results[solver_name]['dt'].append(t[1] - t[0])
            results[solver_name]['error'].append(error_L2)
```

Assuming the error to be of the form $C\Delta t^r$, we can estimate C and r from two consecutive experiments to obtain a sequence of r values which (hopefully) convergences to a value that we can view as the empirical convergence rate of a method. Given the sequence of time steps and errors, a function in the `scitools` package automatically computes the sequence of r values:

```
# Analyze convergence
from scitools.convergencerate import OneDiscretizationPrm
pairwise_rates = OneDiscretizationPrm.pairwise_rates # short form

print '\n\nConvergence results for %d periods' % num_periods
for solver_name in results:
    rates, C = pairwise_rates(results[solver_name]['dt'],
                              results[solver_name]['error'])
    rates = ', '.join(['%.1f' % rate for rate in rates])
    print '%-20s r: %s E_min=%.1E' % \
        (solver_name, rates, min(results[solver_name]['error']))
```

With 4 periods we get

| | |
|--------------------|--------------------------------------|
| ThetaRule(theta=0) | r: 4.2, 2.4, 1.7, 1.3 E_min=1.9E-01 |
| LeapfrogFiltered | r: 10.3, 0.3, 0.5, 0.7 E_min=1.8E-01 |
| ThetaRule(theta=1) | r: 0.2, 0.4, 0.6, 0.8 E_min=1.3E-01 |
| ThetaRule | r: 2.3, 2.0, 2.0, 2.0 E_min=2.1E-03 |
| RK4 | r: 4.0, 4.0, 4.0, 4.0 E_min=1.6E-07 |
| Leapfrog | r: 2.2, 2.0, 2.0, 2.0 E_min=2.1E-03 |
| RK2 | r: 2.3, 2.0, 2.0, 2.0 E_min=2.1E-03 |
| MidpointIter | r: 2.0, 1.0, 2.0, 2.0 E_min=2.1E-03 |

The rates of the Forward and Backward Euler methods (1st and 3rd line) have not yet converged to unity, as expected, while the 2nd-order Runge-Kutta method, Leapfrog, and the θ rule with $\theta = 0.5$ (ThetaRule with default value of `theta`) shows the expected $r = 2$ value. The 4th-order Runge-Kutta holds the promise of being of 4th order, while the filtered Leapfrog method has slow convergence and a fairly large error, which is also evident in the previous figure.

Extending the time domain to 20 periods makes many of the simplest methods inaccurate and the rates computed on coarse time meshes are irrelevant. Also in this case, three of the methods are useless, while the others deliver their promised convergence rates (Forward Euler, i.e., ThetaRule with `theta=0` is left out because of ridiculous results):

| | |
|--------------------|--------------------------------------|
| LeapfrogFiltered | r: 63.7, 0.0, 0.1, 0.2 E_min=4.3E-01 |
| ThetaRule(theta=1) | r: 0.0, 0.1, 0.1, 0.3 E_min=3.8E-01 |
| ThetaRule | r: 3.7, 2.1, 2.0, 2.0 E_min=1.0E-02 |
| RK4 | r: 4.0, 4.0, 4.0, 4.0 E_min=8.0E-07 |
| Leapfrog | r: 0.5, 1.9, 2.0, 2.0 E_min=1.0E-02 |
| RK2 | r: 3.7, 2.1, 2.0, 2.0 E_min=1.0E-02 |
| MidpointIter | r: 1.8, 0.8, 1.9, 2.0 E_min=1.0E-02 |

3.10 Make a Subclass of Problem

Odespy features a module `problems` for defining ODE problems. There is a superclass `Problem` in this module defining what we expect of information about an ODE problem, as well as some convenience functions that are inherited in subclasses. A rough sketch of class `Problem` is listed here:

```
class Problem:
    stiff = False      # classification of the problem is stiff or not
    complex_ = False  # True if f(u,t) is complex valued
    not_suitable_solvers = [] # list solvers that should be be used
    short_description = ''    # one-line problem description

    def __init__(self):
        pass

    def __contains__(self, attr):
        """Return True if attr is a method in instance self."""

    def terminate(self, u, t, step_number):
        """Default terminate function, always returning False."""
        return False

    def default_parameters(self):
        """
        Compute suitable time_points, atol/rtol, etc. for the
        particular problem. Useful for quick generation of test
```

```

        cases, demos, unit tests, etc.
        """
        return {}

    def u_exact(self, t):
        """Implementation of the exact solution."""
        return None

```

Subclasses of `Problem` typically implements the constructor, for registering parameters in the ODE and the initial condition, and a method `f` for defining the right-hand side. For implicit solution method we may provide a method `jac` returning the Jacobian of $f(u, t)$ with respect to u . Some problems may also register an analytical solution in `u_exact`. Here is an example of implementing the logistic ODE from Section 3.2:

```

import odespy

class Logistic(odespy.problems.Problem):
    short_description = "Logistic equation"

    def __init__(self, a, R, A):
        self.a = a
        self.R = R
        self.U0 = A

    def f(self, u, t):
        a, R = self.a, self.R # short form
        return a*u*(1 - u/R)

    def jac(self, u, t):
        a, R = self.a, self.R # short form
        return a*(1 - u/R) + a*u*(1 - 1./R)

    def u_exact(self, t):
        a, R, U0 = self.a, self.R, self.U0 # short form
        return R*U0*numpy.exp(a*t)/(R + U0*(numpy.exp(a*t) - 1))

```

The `stiff`, `complex_`, and `not_suitable_solvers` class variables can just be inherited. Note that `u_exact` should work for a vector `t` so `numpy` versions of mathematical functions must be used.

The initial condition is by convention stored as the attribute `U0` in a subclass of `Problem`, and specified as argument to the constructor.

Here are the typical steps when using such a problem class:

```

problem = Logistic(a=2, R=1E+5, A=1)
solver = odespy.RK4(problem.f)
solver.set_initial_condition(problem.U0)
u, t = solver.solve(time_points)

```

The problem class may also feature additional methods:

```

class MyProblem(odespy.problems.Problem)
    ...
    def constraints(self, u, t):
        """Python function for additional constraints: g(u,t)=0."""

    def define_command_line_arguments(self, parser):

```

```

"""
Initialize an argparse object for reading command-line
option-value pairs. 'parser' is an 'argparse' object.
"""

def verify(self, u, t, atol=None, rtol=None):
    """
    Return True if u at time points t coincides with an exact
    solution within the prescribed tolerances. If one of the
    tolerances is None, return max computed error (infinity
    norm). Return None if the solution cannot be verified.
    """

```

The module `odespy.problems` contains many predefined ODE problems.

3.11 Using Adaptive Methods

The solvers used in the previous examples have all employed a constant time step Δt . Many solvers available through the Odespy interface are adaptive in the sense that Δt is adjusted throughout the solution process to meet a prescribed tolerance for the estimated error.

Simple methods such as RK4 apply time steps

```
dt = time_points[k+1] - time_points[k]
```

while adaptive methods will use several (smaller) time steps than dt in each dt interval to ensure that the estimated numerical error is smaller than some prescribed tolerance. The estimated numerical error may be a rather crude quantitative measure of the true numerical error (which we do not know since the exact solution of the problem is in general not known).

Some adaptive solvers record the intermediate solutions in each dt interval in arrays `self.u_all` and `self.t_all`. Examples include `RKFehlberg`, `Fehlberg`, `DormandPrince`, `CashKarp`, and `BogackiShampine`. Other adaptive solvers (`Vode`, `Lsode`, `Lsoda`, `RKC`, `RKF45`, etc.) do not give access to intermediate solution steps between the user-given time points, specified in the `solver.solve` call, and then we only have access to the solution at the user-given time points as returned by this call. One can run `if solver.has_u_t_all()` to test if the `solver.u_all` and `solver.t_all` arrays are available. These are of interest to see how the adaptive strategy works between the user-specified time points.

The Test Problem. We consider the ODE problem for testing adaptive solvers:

$$u' = -\frac{t-c}{s^2}(u-1) \quad (1)$$

The exact solution is a Gaussian function,

$$u(t) = 1 + \exp\left(-\frac{1}{2}\left(\frac{t-c}{s}\right)^2\right)$$

centered around $t = c$ and width characteristic width ("standard deviation") s . The initial condition is taken as the exact u at $t = 0$.

Since the Gaussian function is significantly different from zero only in the interval $[c - 3s, c + 3s]$, one may expect that adaptive methods will efficiently take larger steps when u is almost constant and increase the resolution when u changes substantially in the vicinity of $t = c$. We can test if this is the case with several solvers.

Running Simple Methods. Let us first use a simple standard method like the 2nd- and 4th-order Runge-Kutta methods with constant step size. With the former method (RK2), $c = 3$, $s = 0.5$, and 41 uniformly distributed points, the discrepancy between the numerical and exact solution in Figure 4 is substantial. Increasing the number of points by a factor of 10 gives a solution much closer to the exact one, and switching to the 4th-order method (RK4) makes the curves visually coincide. The problem is therefore quite straightforward to solve using a sufficient number of points (400) and a higher-order method such as RK4. For curiosity we can mention that the `ForwardEuler` method produces a maximum value of 0.98 with 20,000 points and 0.998 with 200,000 points.

Figure 4: 2nd-order Runge-Kutta method with 41 points.

A simple program testing one numerical method goes as follows (`gaussian1.py`).

```
import odespy, numpy as np, matplotlib.pyplot as plt

center_point = 3
s = 0.5

problem = odespy.problems.Gaussian1(c=center_point, s=s)
```

```

npoints = 41
tp = np.linspace(0, 2*center_point, npoints)

method = odespy.RK2
solver = method(problem.f)
solver.set_initial_condition(problem.U0)

u, t = solver.solve(tp)

method = solver.__class__.__name__
print '%.4f %s' % (u.max(), method)

if solver.has_u_t_all():
    plt.plot(solver.t_all, solver.u_all, 'bo',
             tp, problem.u_exact(tp))
    print '%s used %d steps (%d specified)' % \
          (method, len(solver.u_all), len(tp))
else:
    plt.plot(tp, solver.u, tp, problem.u_exact(tp))
plt.legend([method, 'exact'])
plt.savefig('tmp.png')
plt.show()

```

Running the Runge-Kutta-Fehlberg Method. One of the most widely used general-purpose, adaptive methods for ODE problems is the Runge-Kutta-Fehlberg method of order (4,5). This method is available in three alternative implementations in Odespy: a direct Python version (`RKFehlberg`), a specialization of a generalized implementation of explicit adaptive Runge-Kutta methods (`Fehlberg`), and as a FORTRAN code (`RKF45`). We can try one of these,

```
method = odespy.Fehlberg
```

Figure 5 shows how `Fehlberg` with 40 intervals produces a solution of reasonable accuracy. The dots show the actual computational points used by the algorithm (57 adaptively selected points in time).

Adaptive algorithms apply an error estimate based on considering a higher-order method as exact, in this case a method of order 5, and a method of lower order (here 4) as the numerically predicted solution. The user can specify an error tolerance. In the program above we just relied to the default tolerance, which can be printed by

```
print solver.get()
```

yielding a list of all optional parameters:

```

{'f_kwargs': {}, 'f_args': (),
 'max_step': 1.5000000000000036, 'verbose': 0,
 'min_step': 0.0014999999999999946,
 'first_step': 0.14999999999999999,
 'rtol': 1e-06, 'atol': 1e-08,
 'name of f': 'f', 'complex_valued': False,
 'disk_storage': False, 'u_exact': None}

```

The tolerances involved are of relative and absolute type, i.e.,

```
estimated_error <= tol = rtol*abs(u) + atol
```

Figure 5: Adaptive Runge-Kutta-Fehlberg method with 57 points (starting with 41).

is the typical test on whether the solution is sufficiently. For very small u , `atol` comes into play, while for large u , the relative tolerance `rtol` dominates.

In this particular example, running RK4 with 57 equally spaced points yields a maximum value of 1.95, while `Fehlberg` with 57 adaptively selected points results in 1.98. Note that the tolerances used are 10^{-6} while the real error is of the order 10^{-2} .

We can specify stricter tolerances and also control the minimum allowed step size, `min_step`, which might be too large to achieve the desired error level (`gaussian2.py`):

```
rtol = 1E-12
atol = rtol
min_step = 0.000001

solver = odespy.Fehlberg(problem.f, atol=atol, rtol=rtol,
                          min_step=min_step)
```

The `Fehlberg` solver now applies 701 points and achieves a maximum value of 2.00005. However, RK4 with the same number of (equally spaced) points achieves the same accuracy and is much faster.

Testing More Adaptive Solvers. We have already solved (1) with sufficient accuracy, but let us see how other methods perform, as this will most likely result in a surprise. Below is a program (`gaussian3.py`) that compares several famous and widely used methods in the same plot.

```

import odespy, numpy as np, matplotlib.pyplot as plt

def run(problem, tp, solver):
    method = solver.__class__.__name__

    solver.set_initial_condition(problem.U0)

    u, t = solver.solve(tp)
    solver.u_max = u.max()
    print '%.4f %s' % (solver.u_max, method)

    if solver.has_u_t_all():
        plt.plot(solver.t_all, solver.u_all)
        print '%s used %d steps (%d specified)' % \
            (method, len(solver.u_all), len(tp))
    else:
        plt.plot(solver.t, solver.u)
        legend.append(method)
        plt.hold('on')

rtol = 1E-6
atol = rtol
s = 0.5
npoints = 41
center_point = 3
problem = odespy.problems.Gaussian1(c=center_point, s=s)
tp = np.linspace(0, 2*center_point, npoints)
min_step = 0.0001

methods = ['DormandPrince', 'BogackiShampine',
           'RKFehlberg', 'Vode', 'RK45', 'Lsoda']
solvers = [eval('odespy.' + method)(
    problem.f, atol=atol, rtol=rtol,
    min_step=min_step)
    for method in methods]
# Run Vode with implicit BDF method of order 5
solvers[1].set(adams_or_bdf='bdf', order=5, jac=problem.jac)

legend = []
for solver in solvers:
    run(problem, tp, solver)

plt.plot(tp, problem.u_exact(tp))
legend.append('exact')
plt.legend(legend)
plt.savefig('tmp1.png')

# Plot errors
plt.figure()
exact = problem.u_exact(tp)
for solver in solvers:
    plt.plot(tp, exact - solver.u)
    plt.hold('on')
plt.legend(legend)
plt.savefig('tmp2.png')
plt.show()

```

The default discretization applies $N = 40$ equal-sized time intervals, but adaptive methods should be able to adjust themselves to the desired error level 10^{-6} . Figures 6 and 7 show that this expected behavior is not the case. There

is substantial discrepancy between the methods! Surprisingly, the well-known FORTRAN codes accessed by the `Vode` (`vode.f`) and `Lsoda` (from ODEPACK) methods give very inaccurate results, despite setting `Vode` to use a stiff BDF solver of order 5, and `Lsoda` should automatically select between nonstiff and stiff solvers (of default order 4 in this case).

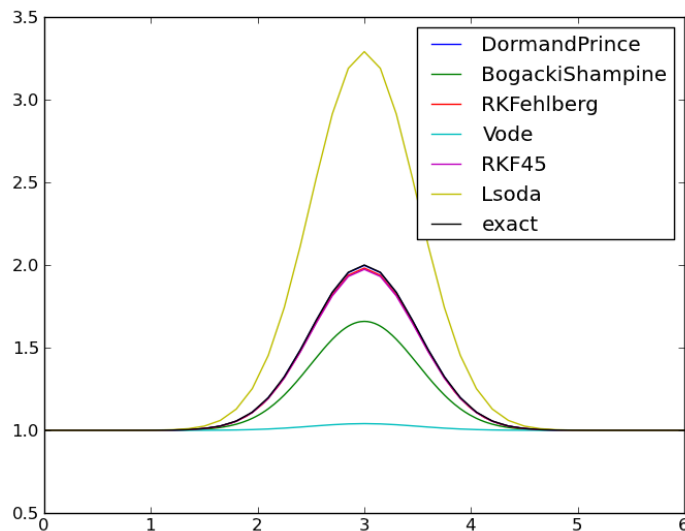

Figure 6: Comparison of adaptive methods with default parameters (tolerance $E-6$).

The program writes out the following results for the maximum value of the solution, which should equal 2:

```
1.9976 DormandPrince
1.6591 BogackiShampine
1.9812 RKFehlberg
1.0406 Vode
1.9734 RKF45
3.2905 Lsoda
```

The clearly most accurate solver among these is `DormandPrince` - the default method used by MATLAB's `ode45` solver, which is perhaps the world's most popular ODE solver.

The remedy to get all the tested solvers to perform well is to choose a much stricter tolerance, say 10^{-10} . Figure 8 shows coinciding curves. Numerically, we now have

```
1.9991 DormandPrince
1.9912 BogackiShampine
1.9942 RKFehlberg
2.0122 Vode
```

Figure 7: Comparison of errors in adaptive methods with default parameters (tolerance E-6).

```
1.9916  RKF45
2.0056  Lsoda
```

For the methods `DormandPrince`, `RKFehlberg`, and `BogackiShampine` we have information about the number of adaptive time points used: 270, 326, and 3307, respectively.

The lesson learned in this example is two-fold: 1) several methods should be tested to gain reliability of the results, and `Odespy` makes such tests easy to conduct, and 2) strict tolerances, far below the default values, may be necessary for some methods, here `Vode` and `Lsoda` in particular. We remark that it is the ODE problem that causes difficulties: changing the problem to `odespy.problems.Logistic` (see the file `logistic9.py`) shows that all the curves coincide and cannot be distinguished visually.

The present test problem with a Gaussian function as solution can be made increasingly more difficult by increasing the value of c/s , i.e., a more peaked function moved to the right.

Extensive Testing. The program `gaussian4.py` sets up an extensive experiments involving a lot of solvers, several c/s values, and several error tolerances. The experiments clearly demonstrate how challenging this ODE problem is for many adaptive solvers unless c/s is moderate and a strict tolerance (much lower than the real accuracy level) is used. One can especially see the fundamental difficulties that `Vode`, `Lsode`, and `Lsoda` (all stiff and nonstiff versions) face when

Figure 8: Comparison of adaptive methods with error tolerance E-10.

$c/s \geq 8$: these solvers do not manage to pick up any variation in u . Nevertheless, for less demanding ODEs these solvers may perform very well, but it is highly recommended to always use the power of the unified Odespy interface to test several different adaptive methods.

3.12 Example: Solving a Complex ODE Problem

Many of the solvers offered by Odespy can deal with complex-valued ODE problems. Consider

$$u' = iwu, \quad u(0) = 1,$$

where $i = \sqrt{-1}$ is the imaginary unit. The right-hand side is implemented as `1j*w*u` in Python since Python applies `j` as the imaginary unit in complex numbers.

Quick Implementation. For complex-valued ODEs, i.e., complex-valued right-hand side functions or initial conditions, the argument `complex_valued=True` must be supplied to the constructor. A complete program reads

```
def f(u, t):
    return 1j*w*u

import odespy, numpy

w = 2*numpy.pi
solver = odespy.RK4(f, complex_valued=True)
solver.set_initial_condition(1+0j)
u, t = solver.solve(numpy.linspace(0, 6, 101))
```

The function `odespy.list_not_suitable_complex_solvers()` returns a list of all the classes in Odespy that are not suitable for complex-valued ODE problems.

Comparison of Methods. We can try three classes that do work for complex-valued ODEs: `Vode`, `RK4`, and `RKFehlberg`. Comparing these with respect to CPU time and final error for a very long time integration of 600 periods is carried out by the following program.

```
def f(u, t):
    return 1j*w*u

import odespy, numpy, time

w = 2*numpy.pi
n = 600 # no of periods
r = 40  # resolution of each period
tp = numpy.linspace(0, n, n*r+1)

solvers = [odespy.Vode(f, complex_valued=True,
                      atol=1E-7, rtol=1E-6,
                      adams_or_bdf='adams'),
            odespy.RK4(f, complex_valued=True),
            odespy.RKFehlberg(f, complex_valued=True,
                              atol=1E-7, rtol=1E-6)]

cpu = []
for solver in solvers:
    solver.set_initial_condition(1+0j)
    t0 = time.clock()
    solver.solve(tp)
    t1 = time.clock()
    cpu.append(t1-t0)

# Compare solutions at the end point:
exact = numpy.exp(1j*w*tp).real[-1]
min_cpu = min(cpu); cpu = [c/min_cpu for c in cpu] # normalize
print 'Exact: u(%g)=%g' % (tp[-1], exact)
for solver, cpu_time in zip(solvers, cpu):
    print '%-15s u(%g)=%.6f (error: %10.2E, cpu: %.1f)' % \
        (solver.__class__.__name__,
         solver.t[-1], solver.u[-1].real,
         exact - solver.u[-1].real, cpu_time)
```

We remark that the solution and the corresponding time values can always be recovered as `solver.u` and `solver.t`, respectively.

The output from the program may read

```
Exact: u(600)=1
Vode      u(600)=1.001587 (error: -1.59E-03, cpu: 1.0)
RK4       u(600)=0.997328 (error:  2.67E-03, cpu: 1.3)
RKFehlberg u(600)=1.000953 (error: -9.53E-04, cpu: 7.5)
```

The `Vode` solver is a wrapper of the FORTRAN code `zvode.f` in `scipy.integrate.ode` and is an adaptive Adams method (with default settings, as used here), `RK4` is a compact and straightforward Runge-Kutta method of order 4 in pure Python with constant step size, and `RKFehlberg` is a pure Python implementation of the adaptive Runge-Kutta-Fehlberg method of order (4,5). These methods give

approximately the same final error, but with different CPU times. We observe that the very simple RK4 solver in pure Python compares favorably with the much more sophisticated FORTRAN subroutine `zvode`.

3.13 Avoiding Callbacks to Python

The ODE solvers that are implemented in FORTRAN calls, by default, the user's Python implementation of $f(u, t)$. Making many calls from FORTRAN to Python may introduce significant overhead and slow down the solution process. When the algorithm is implemented in FORTRAN we should also implement the right-hand side in FORTRAN and call this right-hand side subroutine directly. Odespy offers this possibility.

The idea is that the user writes a FORTRAN subroutine defining $f(u, t)$. Thereafter, `f2py` is used to make this subroutine callable from Python. If we specify the Python interface to this subroutine as an `f_f77` argument to the solver's constructor, the Odespy class will make sure that no callbacks to the $f(u, t)$ definition go via Python.

The Logistic ODE. Here is a minimalistic example involving the logistic ODE from Section 3.2. The FORTRAN implementation of $f(u, t)$ is more complicated than the Python counterpart. The subroutine has the signature

```

subroutine f_f77(neq, t, u, udot)
Cf2py intent(hide) neq
Cf2py intent(out) udot
integer neq
double precision t, u, udot
dimension u(neq), udot(neq)

```

This means that there are two additional arguments: `neq` for the number of equations in the ODE system, and `udot` for the array of $f(u, t)$ that is output from the subroutine.

We write the FORTRAN implementation of $f(u, t)$ in a string:

```

a = 2
R = 1E+5

f_f77_str = """
subroutine f_f77(neq, t, u, udot)
Cf2py intent(hide) neq
Cf2py intent(out) udot
integer neq
double precision t, u, udot
dimension u(neq), udot(neq)
udot(1) = %.3f*u(1)*(1 - u(1)/%.1f)
return
end
""" % (a, R)

```

Observe that we can transfer problem parameters to the FORTRAN subroutine by writing their values directly into the FORTRAN source code. The other alternative would be to transfer the parameters as global (COMMON block) variables to the FORTRAN code, which is technically much more complicated.

Also observe that we need to deal with `udot` and `u` as arrays even for a scalar ODE.

Using `f2py` to compile the string into a Python module is automated by the `odespy.compile_f77` function:

```
import odespy
f_f77 = odespy.compile_f77(f_f77_str)
```

The returned object `f_f77` is a callable object that allows the FORTRAN subroutine to be called as `udot = f_f77(t, u)` from Python. (However, the Odespy solvers will not use `f_f77` directly, but rather its function pointer to the FORTRAN subroutine, and transfer this pointer to the FORTRAN solver. The switching between `t, u` and `u, t` arguments is taken care of. All necessary steps are automatically done behind the scene.)

The solver can be declared as

```
solver = odespy.Lsode(f=None, f_f77=f_f77)
```

Several solvers accept FORTRAN definitions of the right-hand side: `Lsode`, `Lsoda`, and the other ODEPACK solvers, `RKC`, `RKF45`, `Radau5`. Look up the documentation of their `f_f77` parameter to see exactly what arguments and conventions that the FORTRAN subroutine demand.

The file `logistic10.py` contains a complete program for solving the logistic ODE with $f(u, t)$ implemented in Fortran.

Implementing the van der Pol Equation in FORTRAN. As a slightly more complicated example, also involving a subclass of `Problem` and computation of the Jacobian and $f(u, t)$ in FORTRAN, we consider the van der Pol equation,

$$y'' = \mu(1 - y^2)y' - y, \quad y(0) = 2, \quad y'(0) = 1,$$

written as a system as shown in Section 1. We start by implementing a problem class with Python code for $f(u, t)$ and its Jacobian:

```
import odespy

class VanDerPolOscillator(odespy.problems.Problem):
    short_description = "Van der Pol oscillator"

    def __init__(self, U0=[2, 1], mu=3.):
        self.U0 = U0
        self.mu = mu

    def f(self, u, t):
        u_0, u_1 = u
        mu = self.mu
        return [u_1, mu*(1 - u_0**2)*u_1 - u_0]

    def jac(self, u, t):
        u_0, u_1 = u
        mu = self.mu
        return [[0., 1.],
                [-2*mu*u_0*u_1 - 1, mu*(1 - u_0**2)]]
```

Now, we want to provide `f` and `jac` in FORTRAN as well. The FORTRAN code for $f(u, t)$ can be returned from a method:

```

class VanDerPolOscillator(odespy.problems.Problem):
    ...
    def str_f77(self):
        """Return  $f(u,t)$  as Fortran source code string."""
        return """
            subroutine f_f77(neq, t, u, udot)
Cf2py intent(hide) neq
Cf2py intent(out) udot
            integer neq
            double precision t, u, udot
            dimension u(neq), udot(neq)
            udot(1) = u(2)
            udot(2) = %g*(1 - u(1)**2)*u(2) - u(1)
            return
            end
        """ % self.mu

```

While all FORTRAN solvers supported by Odespy so far employ the same signature for the $f(u,t)$ function, different solvers apply different signatures for the Jacobian. Here are two versions for ODEPACK and Radau5, respectively:

```

class VanDerPolOscillator(odespy.problems.Problem):
    ...
    def str_jac_f77_fadau5(self):
        return """
            subroutine jac_f77_radau5(neq,t,u,dfu,ldfu,rpar,ipar)
Cf2py intent(hide) neq,rpar,ipar
Cf2py intent(in)    t,u,ldfu
Cf2py intent(out) dfu
            integer neq,ipar,ldfu
            double precision t,u,dfu,rpar
            dimension u(neq),dfu(ldfu,neq),rpar(*),ipar(*)
            dfu(1,1) = 0
            dfu(1,2) = 1
            dfu(2,1) = -2*%g*u(1)*u(2) - 1
            dfu(2,2) = %g*(1-u(1)**2)
            return
            end
        """ % (self.mu, self.mu)

    def str_jac_f77_lsode_dense(self):
        return """
            subroutine jac_f77(neq, t, u, ml, mu, pd, nrowpd)
Cf2py intent(hide) neq, ml, mu, nrowpd
Cf2py intent(out) pd
            integer neq, ml, mu, nrowpd
            double precision t, u, pd
            dimension u(neq), pd(nrowpd,neq)
            pd(1,1) = 0
            pd(1,2) = 1
            pd(2,1) = -2*%g*u(1)*u(2) - 1
            pd(2,2) = %g*(1 - u(1)**2)
            return
            end
        """ % (self.mu, self.mu)

```

For the Lsode solver we can also provide the Jacobian in banded matrix format (this is not yet supported for Radau5, but the underlying FORTRAN code allows a banded Jacobian).

Having some methods returning FORTRAN code, we need to turn the source code into Python modules. This is done by `odespy.compile_f77` in the constructor of class `VanDerPolOscillator`:

```
class VanDerPolOscillator(odespy.problems.Problem):

    def __init__(self, U0=[2, 1], mu=3.):
        self.U0 = U0
        self.mu = mu

        # Compile F77 functions
        self.f_f77, self.jac_f77_radau5, self.jac_f77_lsode = \
            compile_f77([self.str_f_f77(),
                        self.str_jac_f77_radau5(),
                        self.str_jac_f77_lsode()])
```

The application of this problem class goes as follows:

```
problem = VanDerPolOscillator()
import odespy
solver = odespy.Radau5(f=None, f=problem.f_f77,
                      jac=problem.jac_f77_radau5)
solver.set_initial_condition(problem.U0)
u, t = solver.solve(time_points)
```

3.14 Example: Solving a Stochastic Differential Equation

We consider an oscillator driven by stochastic white noise:

$$x''(t) + bx'(t) + cx(t) = N(t), \quad x(0) = X, \quad x'(0) = 0,$$

where $N(t)$ is the white noise function computed numerically as

$$N(t_i) \approx \sigma \frac{\Delta W_i}{\sqrt{t_{i+1} - t_i}},$$

where $\Delta W_1, \Delta W_2, \dots$ are independent normally distributed random variables with mean zero and unit standard deviation, and σ is the strength of the noise. The physical feature of this problem is that $N(t)$ provides an excitation containing "all" frequencies, but the oscillator is a strong filter: with low damping one of the frequencies in $N(t)$ will hit the resonance frequency $\sqrt{c}/(2\pi)$ which will then dominate the output signal $x(t)$.

The noise is additive in this stochastic differential equation so there is no difference between the Ito and Stratonovich interpretations of the equation.

The challenge with this model problem is that stochastic differential equations do not fit with the user interface offered by Odespy, since the right-hand side function is assumed to be dependent only on the solution and the present time ($\mathbf{f}(\mathbf{u}, \mathbf{t})$), and additional user-defined parameters, but for the present problem the right-hand side function needs information about $N(t)$ and hence the size of the current time step.

We can solve this issue by having a reference to the solver in the right-hand side function, precomputing $N(t_i)$ for all time intervals i , and using the `n` attribute in the solver for selecting the right force term (recall that some

methods will call the right-hand side function many times during a time interval - all these calls must use the same value of the white noise).

The right-hand side function must do many things so a class is appropriate:

```
class WhiteNoiseOscillator:
    def __init__(self, b, c, sigma=1):
        self.b, self.c, self.sigma = b, c, sigma

    def connect_solver(self, solver):
        """Solver is needed for time step number and size."""
        self.solver = solver

    def f(self, u, t):
        if not hasattr(self, 'N'): # is self.N not yet computed?
            # Compute N(t) for all time intervals
            import numpy
            numpy.random.seed(12)
            t = self.solver.t
            dW = numpy.random.normal(loc=0, scale=1, size=len(t)-1)
            dt = t[1:] - t[:-1]
            self.N = self.sigma*dW/numpy.sqrt(dt)

        x, v = u
        N = self.N[self.solver.n]
        return [v, N -self.b*v -self.c*x]
```

Note that $N(t)$ is computed on demand the first time the right-hand side function is called. We need to wait until the `f` method is called since we need access to the solver instance to compute the `self.N` array.

It is easy to compare different methods for solving this stochastic equation:

```
problem = WhiteNoiseOscillator(b=0.1, c=pi**2, sigma=1)
solvers = [odespy.Heun(problem.f), odespy.RK4(problem.f),
            odespy.ForwardEuler(problem.f)]
for solver in solvers:
    f.connect_solver(solver)
    solver.set_initial_condition([0,0]) # start from rest
    T = 60 # with c=pi**2, the period is 1
    u, t = solver.solve(linspace(0, T, 10001))

    x = u[:,0]
    plot(t, x)
    hold(True)

legend([str(s) for s in solvers])
```

All solutions are also stored in the solver objects as attributes `u` and `t`, so we may easily extract the solution of RK4 by

```
solvers[1].u, solvers[1].t
```

The `Heun` and `RK2` methods give coinciding solutions while the `ForwardEuler` method gives too large amplitudes. The frequency is 0.5 (period 2) as expected.

In this example the white noise force is computed only once since the `f` instance is reused in all methods. If a new `f` is created for each method, it is crucial that the same seed of the random generator is used for all methods, so

Figure 9: Oscillator driven by white noise.

that the time evolution of the force is always the same - otherwise the solutions will be different.

The complete code is available in [sode.py](#).

4 Inner Workings of the Package

There are three basic entities when solving ODEs numerically: the definition of the *ODE system*, the *time-stepping method*, and the *solver* that runs the "time loop" and stores results.

The information about the ODE system is made very simple: the user provides 1) an object that can be called as a Python function $f(u, t)$, and 2) an array or list with the initial values. Some users will store this information in their own data structures, e.g., a class.

The time-stepping method and the algorithm for calling the time-stepping are collected in a solver class. All the solver classes are related in a class hierarchy. Each solver class is initialized by the right-hand side function (f) and an optional set of parameters for controlling various parts of the solution process. The solver object is also used to set the initial condition (`set_initial_condition`) and to run the solution process (`solve`). The time-stepping scheme is normally isolated in a method `advance` in the solver classes, but for some schemes or external software packages the separation of doing one step and doing the whole time integration is less feasible. In those cases, `solve` will mix the time-stepping loop and the numerical scheme.

The package does not interact with visualization tools - the array containing the solution is returned to the user and must be further processed and visualized in the user's code.

Below we describe how the classes in the solver hierarchy work and how parameters are registered and initialized.

4.1 Solver Parameters

The `solver` module defines a global dictionary `_parameters` holding all legal parameters in Odespy classes. These are parameters that the user can adjust. Other modules import this `_parameters` dict and update it with their own additional parameters.

For each parameter the `_parameters` dict stores the parameter name, a default value, a description, the legal object type for the value of the parameter, and other quantities if needed. A typical example is

```
_parameters = dict(
...

f = dict(
    help='Right-hand side f(u,t) defining the ODE',
    type=callable),

f_kwargs = dict(
    help='Extra keyword arguments to f: f(u, t, *f_args, **f_kwargs)',
    type=dict,
    default={}),

theta = dict(
    help='theta in [0,1] used for'\
    ' "theta-rule" finite difference approx.',
    default=0.5,
    type=(int,float),
    range=[0, 1])
```

```
}..
```

Each solver class defines a (static) class variable `_required_parameters` for holding the names of all required parameters (in a list). In addition, each solver class defines another class variable `_optional_parameters` holding the names of all the optional parameters. The doc strings of the solver classes are automatically equipped with tables of required and optional parameters.

The optional parameters of a class consist of the optional parameters of the superclass and those specific to the class. The typical initialization of `_optional_parameters` goes like this:

```
class SomeMethod(ParentMethod):
    _optional_parameters = ParentMethod._optional_parameters + \
        ['prm1', 'prm2', ...]
```

where `prm1`, `prm2`, etc. are names registered in the global `_parameters` dictionary.

From a user's point of view, the parameters are set either at construction time or through the `set` function:

```
>>> from odespy import RK2
>>> def f(u, t, a, b=0):
...     return a*u + b
...
>>> solver = RK2(f, f_kwargs=dict(b=1))
>>> solver.f_kwargs
{'b': 1}
>>> solver.set(f_args=(3,))
>>> solver.f_args
(3,)
>>> # Get all registered parameters in the method instance
>>> solver.get()
{'f_kwargs': {'b': 1}, 'f_args': (3,), 'complex_valued': False,
'name of f': 'f'}
```

The `set` method sets parameters through keyword arguments and can take an arbitrary collection of such arguments:

```
solver.set(name1=value1, name2=value2, name3=value3, ...)
```

The `get` method returns the parameters and their values as a dictionary. We remark that the `'f'` key, which one might expect to appear in the returned dictionary of parameters, are omitted because it is always a lambda function wrapping the user's `f` function such that the returned value is guaranteed to be a `numpy` array. Instead, there is an entry `'name of f'` which reflects the name of the user-supplied function. The same comment applies to the `jac` parameter for specifying the Jacobian used in implicit methods.

4.2 Solver Classes

Each solver in this package is implemented as a class in a class hierarchy. Basic, common functionality is inherited from super classes, and the actual solver class implements what is specific for the method in question.

The Inherited Superclass Constructor. Class `Solver` is the super class of the hierarchy. Subclasses normally just inherit their constructor from class `Solver`. This constructor requires one mandatory argument: the right-hand side of the ODE, $f(u, t)$, coded as a Python function `f(u, t)`. Some solvers implemented in FORTRAN allows `f` to be a wrapper of a FORTRAN function defining the right-hand side, but such a wrapper is specified through the `f_f77` argument and using `None` for `f`. The constructor accepts a range of additional keyword arguments for setting parameters of the solver. Which keyword arguments that are available depends on what the subclass has registered as legal parameters in `_optional_parameters` and `_required_parameters`.

The constructor performs a set of tasks that are common to all the subclass solvers:

1. The set of optional and required parameters of a particular solver is loaded into `self._parameters` such that this dictionary can be used to look up all parameters of the solver.
2. The solver-specific method `adjust_parameters` is called to allow the programmer of a solver to manipulate `self._parameters`. For example, some parameters may be modified or set according to the value of others.
3. Entries in `self._parameters` are mirrored by class attributes. The computations and the `set` and `get` methods will make use of the attributes rather than the `self._parameters` dict to extract data. For example, the value of `self._parameters['myvar']` becomes available as `self.myvar` and in the algorithms we use `self.myvar`, perhaps with a test `hasattr(self, 'myvar')` test or a `try-‘except’` clause (catching an `AttributeError`).
4. The `set` method is called with all keyword arguments given to the constructor, which then modifies the default values of the parameters and sets the corresponding attributes.
5. The `f` function is wrapped in a lambda function such that `f(u, t)` is guaranteed to return an array (in case the user returns a list or scalar for convenience). The same is done with the Jacobian (`jac`) and other user-defined callback functions.
6. The `initialize` method is called to finalize the tasks in the constructor. The most common use of this method in subclasses is to import extension modules that the solver depends on and provide an error message if the extension modules are not available. If they are, the modules are normally stored through an attribute of the subclass.

Useful Methods. Let `solver` be some instance of a subclass in the hierarchy. The following methods are sometimes useful:

- `repr(solver)`: return the subclass name along with all registered parameters and their values. This string provides complete information on the initialization of a solver.
- `str(solver)`: return a short pretty print string reflecting the name of the method and the value of parameters that must be known to uniquely define the numerical method. This string is what one would use as legends in a plot or as method identifier in a table.
- `solver.get_parameter_info()`: return or print all registered parameters for the current solver and all properties for each parameter.
- `solver.switch_to(name)`: return a new solver of type `name`, initialized with all parameters of the current solver that are legal in the new solver. The method is useful when trying out a range of solvers for a problem.

The Solve Method. After the constructor is called, `solver.set_initial_condition` is called to set the initial condition, and then `solve` is called. The `solve` method features the following steps:

1. Call `initialize_for_solve` (implemented in subclasses) to precompute whatever is needed before the time loop. The super class allocates storage for the solution and loads the initial condition into that data structure. Any subclass implementation of `initialize_for_solve` must therefore also call this method in its super class.
2. Call `validate_data` to check if the data structures are consistent before starting the computations. Subclass implementations of this method must call the super class' version of the method.
3. Run a loop over all time levels `n` and call `advance` (implemented in subclasses) at each level to advance the solution from time `t[n]` to `t[n+1]`. Also call `terminate` so that the user code can analyze, work with the solution, and terminate the solution process.

Some subclasses will override the `solve` method and provide their own, but most subclasses just inherits the general one and implements the `advance` method.

Solver Attributes. All classes have a set of attributes:

1. `users_f`: holds the user's function for $f(u, t)$. Implicit solvers may have a corresponding `users_jac` for the user's Jacobian.
2. One attribute for each parameter in the class.
3. `u`: 1D `numpy` array holding the solution for a scalar ODE and a 2D array in case of a system of ODEs. The first index denotes the time level.
4. `t`: the time levels corresponding to the first index in the `u` array.

5. `quick_description`: a short one-line description of the method (this variable is static in the class, i.e., declared outside any method).

Most classes will also define two additional static variables, `_required_parameters` and `_optional_parameters` as explained in Section 4.1.

Other Superclasses. There are superclasses `SolverImplicit` for implicit methods, `Adaptive` for adaptive methods, `RungeKutta1level` for general, explicit 1-level Runge-Kutta methods, `RungeKutta2level` for general, explicit, adaptive 2-level Runge-Kutta methods, `ode_scipy` for interfaces to ODE solvers in `scipy`, and `Odepack` for interfaces to the ODEPACK family of solvers.

4.3 A Very Simple Subclass

To implement a simple explicit scheme for solving a scalar ODE or a system of ODEs, you only need to write a subclass of `Solver` with an `advance` method containing the formula that updates the solution from one time level to the next. For example, the Forward Euler scheme reads

$$u_{n+1} = u_n + \Delta t f(u_n, t_n),$$

where subscript n denotes the time level, and $\Delta t = t_{n+1} - t_n$ is the current time step. The implementation goes like

```
class ForwardEuler(Solver):
    """
    Forward Euler scheme::

        u[n+1] = u[n] + dt*f(u[n], t[n])
    """
    quick_description = 'The simple explicit (forward) Euler scheme'

    def advance(self):
        u, f, n, t = self.u, self.f, self.n, self.t
        dt = t[n+1] - t[n]
        unew = u[n] + dt*f(u[n], t[n])
        return unew
```

Remarks:

1. The `quick_description` string is necessary for the class to appear in the automatically generated overview of implemented methods (run `pydoc odespy` to see this table).
2. Extracting class attributes in local variables (here `u`, `f`, etc.) avoids the need for the `self` prefix so that the implemented formulas are as close to the mathematical formulas as possible.

Almost equally simple schemes, like explicit Runge-Kutta methods and Heun's method are implemented in the same way (see `solvers.py`).

4.4 A Subclass with More Code

A 2nd-order Adams-Bashforth scheme is a bit more complicated since it involves three time levels and therefore needs a separate method for the first step. We should also avoid unnecessary evaluations of $f(u, t)$. The user can specify a parameter `start_method` for the name of the solver to be used for the first step. This solver is initialized by the `switch_to` method in class `Solver`. Basically,

```
new_solver = solver.switch_to(solver_name)
```

creates a new solver instance `new_solver`, of the class implied by `solver_name`, where all relevant parameters from `solver` are copied to `new_solver`.

An implementation of a subclass for the 2nd-order Adams-Bashforth scheme can then look as follows.

```
class AdamsBashforth2(Solver):
    """
    Second-order Adams-Bashforth method::

         $u[n+1] = u[n] + dt/2 \cdot (3f(u[n], t[n]) - f(u[n-1], t[n-1]))$ 

    for constant time step  $dt$ .

    RK2 is used as default solver in first step.
    """
    quick_description = "Explicit 2nd-order Adams-Bashforth method"
    _optional_parameters = Solver._optional_parameters + \
        ['start_method',]

    def initialize_for_solve(self):
        # New solver instance for first step
        self.starter = self.switch_to(self.start_method)
        Solver.initialize_for_solve(self)

    def validate_data(self):
        if not self.constant_time_step():
            print '%s must have constant time step' % self.__name__
            return False
        else:
            return True

    def advance(self):
        u, f, n, t = self.u, self.f, self.n, self.t

        if n >= 1:
            dt = t[n+1] - t[n] # must be constant
            self.f_n = f(u[n], t[n])
            unew = u[n] + dt/2 * (3*self.f_n - self.f_n_1)
            self.f_n_1 = self.f_n
        else:
            # User-specified method for the first step
            self.starter.set_initial_condition(u[n])
            time_points = [t[n], t[n+1]]
            u_starter, t_starter = self.starter.solve(time_points)
            unew = u_starter[-1]
            self.f_n_1 = f(u[0], t[0])
```

```
return unew
```

Three features are worth comments: 1) we extend the set of optional parameters; 2) we must initialize a separate solver for the first step, and this is done in the `initialize_for_solve` method that will be called as part of `solve` before the time stepping; and 3) we extend `validate_data` to check that the time spacing given by the `time_points` argument to `solve` is constant. The utility method `constant_time_step` provided in super class `Solver` carries out the details of the check.

More advanced implementations of subclasses can be studied in the `solvers.py` and `RungeKutta.py` files.

4.5 A Simple Example of an Implicit Method

Class `SolverImplicit` acts as superclass for the implementation of implicit methods. This class provides some basic functionality for solving the system of nonlinear equations that normally arises in implicit methods by Picard or Newton iteration. The parameter `nonlinear_solver` can take the values `Picard` or `Newton`. The user must in case of Newton's method provide a `jac` parameter for a function evaluating the Jacobian of $f(u, t)$ with respect to u : $J_{i,j} = \partial f_i / \partial u_j$.

Instead of implementing an `advance` method in subclasses, one provides a method `Picard` and/or `Newton` to define key quantities in these methods. The superclass implements `advance`, which will run a Picard or Newton iteration. The `Picard` method returns all the terms on the right-hand side of the discrete equation when only `u[n+1]` is on the left-hand side. `Newton` returns the right-hand side and the Jacobian of the system to be solved in each Newton iteration.

Here is an example showing the complete code of the Backward Euler method.

```
class BackwardEuler(SolverImplicit):
    """
    Implicit Backward Euler method::

        u[n+1] = u[n] + dt*f(t[n+1], u[n+1])

    The nonlinear system is solved by Newton or Picard iteration.
    """
    quick_description = "Implicit 1st-order Backward Euler method"

    def Picard_update(self, ukp1):
        u, f, n, t = self.u, self.f, self.n, self.t
        dt = t[n+1] - t[n]
        return u[n] + dt*f(ukp1, t[n+1])

    def Newton_system(self, ukp1):
        u, f, n, t = self.u, self.f, self.n, self.t
        dt = t[n+1] - t[n]
        F = ukp1 - (u[n] + dt*f(ukp1, t[n+1]))
        J = np.eye(self.neq) - dt*self.jac(ukp1, t[n+1])
        return F, J
```

5 Troubleshooting

Constructor takes exactly two arguments, 5 given. Constructors in the `Solver` hierarchy take only the `f` function as positional argument. All other parameters to the constructor must be keyword arguments.

Remark. This document was written with aid of the [Doconce](#) tool, which allows output in many different formats.
